ABSTRACT

Intestinal parasitic infections are a common health problem among Amerindian populations and schistosomiasis represents one of the most prevalent diseases in Maxakali people. The Kato-Katz is the diagnostic method recommended by WHO for epidemiological studies; however, one of the technique's limitations is the failure to detect parasites in individuals with low parasite load. The aim of this study was to establish the prevalence of *Schistosoma mansoni* in indigenous Maxakali villages, evaluating the TF-Test[®] performance for diagnosis compared to the Kato-Katz technique. Stool samples from 545 individuals were processed by the TF-Test[®] (1 sample) and Kato-Katz (1 slide). The positivity rate for *S. mansoni* by Kato-Katz was 45.7%. The rate by the TF-Test[®] was 33.2%, and 51.9% by the combined parasitological techniques. The amplitude of parasite load was 24 to 4,056 eggs per gram of feces (epg), with a geometric mean of 139 epg. The co-positivity, co-negativity, and accuracy values by TF-Test[®] in relation to Kato-Katz were 59.0%, 88.5%, and 75.0%, respectively. The agreement between these techniques was moderate ($k=0.486$) as determined by the kappa index. Thus, the results of this study demonstrated that the performance of Kato-Katz was superior ($p < 0.05$) to that of TF-Test[®] in the detection of *S. mansoni*. The combination of TF-Test[®] and Kato-Katz resulted in an increased positivity rate of *S. mansoni*, demonstrating the high risk of infection to which indigenous populations are exposed and the importance of the implementation of control strategies in Maxakali villages.

KEYWORDS: Schistosomiasis. Parasitological techniques. Helminthes. Indigenous populations. Prevalence.

INTRODUCTION

Schistosomiasis mansoni continues to be a serious public health problem in Brazil as it is one of the waterborne diseases with a highest prevalence¹. The diagnosis of *Schistosoma mansoni* infection is primarily made through parasitology stool tests, in which the eggs released by the adult female worm are investigated. The Kato-Katz² technique is recommended by WHO³ for epidemiological studies. However, one of this technique's limitations is the failure to detect the parasite in areas of low endemicity and when infected individuals have low parasite load^{4,5}. Due to the low positivity of Kato-Katz in the above-mentioned situation, several authors have proposed new diagnostic methods to increase the diagnosis sensitivity on the field, such as TF-Test[®] (Three Fecal Test)⁶, which, in a single step, centrifuges and filters stool samples in formaldehyde-ethyl acetate and concentrates the samples by sedimentation. The rapid diagnosis test proposed by Mello-Silva et al.⁷, a modified

Kato-Katz technique by adding sodium acetate formalin (SAF) as a qualitative promotes the clarification of samples to facilitate egg visualization. The FLOTAC technique⁸, which also uses SAF, is more sensitive for the detection of protozoan and helminthes infections than the Kato-Katz. Therefore, the search for more sensitive diagnostic methods is necessary to obtain a more accurate diagnosis. Applying different parasitology stool tests would be a feasible alternative to overcoming this problem. In addition to parasitological techniques, a diagnosis can be made through immunological and molecular methods, both of which are more sensitive^{9,10}, but are not feasible in epidemiological studies, especially due to the high cost of reagents and equipment. The Point-of-care-circulating Cathodic Antigen (POC-CCA[®]) has been recently evaluated and is based on the direct detection of the parasite's CCA antigen in the host's urine (Rapid Medical Diagnostics, Pretoria, South Africa). Accuracy studies of this test are being conducted to assess its diagnostic performance in areas of low endemicity and in individuals with low parasite burden¹¹.

The Maxakali ethnic group is one of the indigenous communities in the Minas Gerais State that still maintain many of its cultural aspects¹². Schistosomiasis affects a large part of this population due to lack of basic sanitation, the presence of intermediate hosts and cultural habits that favor the parasite's dispersion. Results by Assis et al.¹² point to poor sanitation conditions in these villages, as can be seen by the use of water from rivers and ponds, without any prior treatment, and the absence of an adequate sewage system.

The TF-Test[®] represents a diagnostic alternative because it is able to detect eggs and larvae of helminthes and protozoan cysts. This test is suitable for individual diagnosis, epidemiological surveys, or chemotherapy evaluation in treated communities⁶. TF-Test[®] allows the storage of stool samples for 30 days. Also, the samples can be safely transported when collected in remote areas¹³. In this study, we compared the performance of this technique for diagnosing schistosomiasis mansoni in Maxakali villages in relation to the Kato-Katz technique, a widely used parasitological method in epidemiological studies. In this way, we proposed to evaluate the sensitivity of a minimum diagnosis by associating a qualitative method with a quantitative method.

MATERIAL AND METHODS

Study area and population

Indigenous people of the Maxakali ethnic group are distributed in the municipalities of Santa Helena de Minas,

Bertópolis, Ladainha and in the district of Topazio in the municipality of Teófilo Otoni, where the following health centers are located: Agua Boa, Pradinho, Aldeia Verde and Cachoerinha, respectively, all of them in the Northeast region of Minas Gerais¹⁴. This study was carried out in 2014-2015. The target population included the indigenous population living in the Agua Boa and Pradinho health centers totaling 545 individuals who agreed to participate in the study, 296 (54.3%) female and 249 (45.7%) males.

Inclusion and exclusion criteria

This study included all of the individuals living in the aforementioned villages, of both sexes, aged 0 to 86 years, who agreed to participate in the research and where the leaderships of each village had signed a document authorizing the research. From the 1,642 Maxakali people, 1,026 did not agree to take part of the research/study and 71 failed to successfully finish or failed to accomplish the two diagnostic tests, totaling 545 individuals who agreed to participate in the study.

Diagnostic techniques

Vials for stool specimen collection were distributed to each participant and one sample was returned by each individual.

Kato-Katz – This technique was carried out using the Helmtest[®] kit (Biomanguinhos, FIOCRUZ, Rio de Janeiro, RJ, Brazil) and following the manufacturer's instructions. One slide was analyzed per individual, which corresponds to 41.7 mg of feces.

Intensity of infection – The worm burden was determined as eggs per gram of feces (epg) according to WHO³ classification. The value of the individual intensity of infection was obtained according to the Kato-Katz method using the arithmetic mean of eggs found on each slide multiplied by 24, and the population intensity infection was determined by geometric mean².

TF-Test[®] – A portion of feces (about 1 g) was placed in a tube containing preservative solution (10% formalin), which was processed using 3 mL of ethyl acetate and a drop of a neutral detergent, as recommended by the manufacturer (Bio-Brasil Biotecnologia, Anapolis, Goiás State, Brazil). This tube was connected to the centrifuge tube and centrifuged at 500 g for 1 min and 30 s in a Laborline – Elektra GoldLine centrifuge. The supernatant was discarded and the total sediment was re-suspended in distilled water and analyzed using optical microscopy (10x e 40x magnification). Three slides containing aliquots of sediment were examined for identification of *S. mansoni*

eggs and analyzed in a qualitative way, i.e., there was no quantification of the parasite's eggs per gram of feces.

Statistical analysis

OpenEpi software, version 3.03 (www.OpenEpi.com), was used for statistical analysis. Co-positivity, co-negativity, and accuracy values were calculated with 95% confidence intervals (CIs) for the TF-Test® technique. Co-positivity was calculated by the proportion of positive results in both techniques divided by the total number of true positives. Co-negativity was calculated by the proportion of negative results in both techniques divided by the total number of true negatives. Accuracy was calculated by the proportion of true positives and true negatives divided by the total number of evaluated individuals. The gold standard was defined by the sum of positive results for *S. mansoni* by both parasitological techniques. The level of agreement between different diagnostic techniques was determined by the Kappa coefficient¹⁵. The comparison between proportions was calculated by the paired McNemar test and the adopted significance level was 0.05.

Ethical considerations

This study was approved by indigenous leaders, who signed an informed consent form representing all residents in the villages and by the Research Ethics Committee of the Federal University of Ouro Preto (process N° 2005/58), the National Commission for Research Ethics (CONEP, process N° 902/2006), and the National Foundation of the Indian (FUNAI; Authorization N° 73/CGEP/06).

RESULTS

The combined use of Kato-Katz and TF-Test® (the “gold standard”) was able to detect eggs of *S. mansoni* in 51.9% (283 of 545) of the stool samples. The positivity rate examining only one Kato-Katz slide was 45.7% (249 of 545) and one TF-Test® sample was 33.2% (181/545) ($p < 0.05$). The co-positivity was 59% (CI: 52.8-64.9%), the co-negativity 88.5% (CI: 84.4-91.7%), and the accuracy,

75% (CI: 71.2-78.5%). The agreement between both diagnostic techniques determined by kappa index was moderate ($k=0.486$) (Table 1).

In the Kato-Katz technique, the number of eggs detected per gram of feces varied from 24 to 4,056 egg, with a geometric mean equal to 139 egg, classified as a medium parasite load. The parasite load was low (1 to 99 egg) in 46.2% (115/249) of individuals, medium (100 to 399 egg) in 28.9% (72/249), high (400 to 999 egg) in 15.3% (38/249), and very high (above 1,000 egg) in 9.6% (24/249) (Figure 1).

Figure 1 - Relative frequency of positivity by the Kato-Katz technique in relation to worm burden

The results presented in Figure 2 have shown that infected individuals with high parasite burden detected by Kato-Katz had a 2.5-fold increase in the positivity rate obtained by the TF-Test, relative to those with low parasite burden. Among those with a negative result by the Kato-Katz technique, 11.5% were detected by the TF-Test®.

Positivity rates according to the age groups and assessed by the three diagnostic methods are shown in Figure 3. As expected, the “gold standard” results showed the highest positivity rates regardless of the age

Table 1 – Evaluation of performance parameters of the TF-Test® considering Kato-Katz as the “gold standard”

	Kato-Katz			Co-positivity (%) (CI 95%)	Co-negativity (%) (CI 95%)	Accuracy (%) (CI 95%)	Kappa Index	
	Positive	Negative	Total					
TF-Test®	Positive	147	34	181 (33.2%)*	59.0 (52.8-64.9)	88.5 (84.4-91.7)	75.0 (71.25 - 78.5)	0.486 (0.4049-0.5672)
	Negative	102	262	364				
	Total	249 (45.7%)*	296	545				

* McNemar test = 34.0, $p < 0.001$.

Worm burden according to Kato-Katz technique expressed in eggs per gram of feces (epg)

Figure 2 - Positivity rate for *S. mansoni* according to the TF-Test® in relation to worm burden obtained by the Kato-Katz technique, Maxakali indigenous people, 2014-2015. Low: 1 – 99 epg; Medium: 100 – 399 epg; High: 400 – 999 epg; Very high: ≥1000 epg. (WHO, 2002)

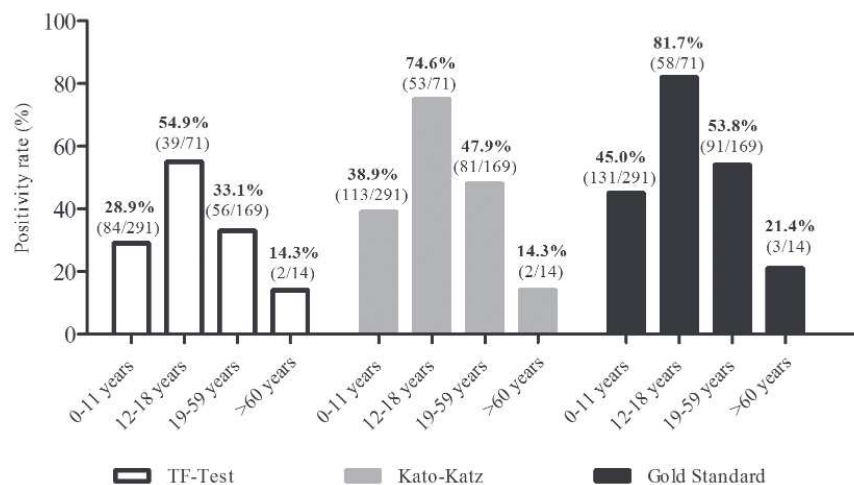

Figure 3 - Positivity rate (%) for schistosomiasis according to age group and diagnostic methods, Maxakali indigenous people, 2014-2015

group, 45% (131/291) in the 0 -11 yearsold group, 81.7% (58/71) in 12-18 group, 53.8% (91/169) in 19-59group , and 21.4% (3/14) in ≥ 60 group. The higher positivity in the 12-18 years old group was followed by a reduction as age increased.

Positivity rates for schistosomiasis according to age group and gender obtained by the “gold standard” are shown in Figure 4. The highest positivity rate (87.5%) was observed among females between 12 and 18 years old. Among the elderly, positivity was observed only in females (30%). The positivity was 57.4% (n=170) in females and 45.4% (n=113) in males. According to the Kato-Katz technique, the female positivity rate was 51% and in males, 39.4%. Using the TF-Test® these rates were 38.9% and 26.5% for males and females, respectively.

DISCUSSION

Diagnosis of *S. mansoni* infection has traditionally been carried out by parasitological methods such as the Kato-Katz technique², which provides good sensitivity in highly endemic areas and has been widely applied in epidemiological surveys due to its favorable cost-benefit and practicality in precarious laboratory infrastructure situations, since it is a quantitative technique and allows the concomitant diagnosis of other helminths^{4,16}. However, in low prevalence situations, in individuals presenting low infection intensity, as well as in the evaluation of cure after specific treatment, this technique has been less sensitive^{4,5,10}.

The innovative proposal of the TF-Test® technique is based on the centrifugal sedimentation of feces in

Figure 4 - Positivity rate for schistosomiasis according to age group and gender obtained by the Gold Standard*. *Gold Standard: Results obtained by the combination of Kato-Katz and TF-Test® techniques

formaldehyde-ethyl acetate. The differential of this technique in relation to others is its high diagnostic sensitivity for helminthes and protozoa⁶. This could be attributed to the technique affording high parasitic concentration, when processing three fecal samples collected on different days, in a single step. In this study, only one fecal sample per individual was used to conduct a comparative evaluation between methods, aimed at greater compliance by the participants and reducing logistic problems in carrying out the study. Moreover, the one fecal sample procedure was designed to evaluate the effectiveness of TF-Test® associated with Kato-Katz to estimate the schistosomiasis mansoni prevalence in vulnerable populations.

The use of a single fecal sample to perform the TF-Test® can be justified by the logistic limitations to carry out sampling on alternate days in the field work, as recommended by the manufacturer. A previous study in the same ethnic group has reported inadvertent ingestion of the formaldehyde from TF-Test® tubes by some study participants¹². For this reason, one single sample was used to evaluate the effectiveness of TF-Test® in the present study. The sample was collected in regular plastic containers and transferred to the TF-Test® tube by the health care team, on the same day. A decrease in sensitivity to detect parasite infection was expected when using one fecal sample compared to multiple samples. However, the combination of two methods is expected to compensate this lack of sensitivity. These results demonstrated that this strategy is feasible in indigenous villages presenting the same problem and exposed to a high risk of infection with intestinal parasites.

The TF-Test® technique presented a lower positivity rate for *S. mansoni* (33.2%) than that obtained by a slide analyzed

by the Kato-Katz technique (45.7%), taking into account the sensitivity of only 59% and a moderate agreement (kappa index: 0.486) in relation to the Kato-Katz technique. Our data corroborate the findings of Siqueira et al.⁵ and differ from those obtained by Gomes et al.⁶ and Carvalho et al.¹³, who found that the TF-Test® had higher positivity rates in detecting both protozoa and helminthes in human stool samples as compared with the conventional Kato-Katz. These results could be explained by the recommended use of three stool samples from each subject collected on alternate days followed by these authors, whereas in this study, a single fecal sample per individual was used to perform the test. According to Assis et al.¹², the prevalence of *S. mansoni* determined by the TF-Test®, using three fecal samples on alternating days, was 23.7% for the entire Maxakali Indigenous Land, 17.6% for the Agua Boa Base Center, and 23.9% for the Pradinho Base Center, both lower than the 33.2% obtained in this study. Some factors may justify the positivity rate obtained by the TF-Test® technique in these areas. Although the amount of fecal material used by this technique is greater, parasitic forms are probably lost during processing¹⁷ and also because fecal debris causes the slide to be dirtier, making it difficult to visualize the parasite's eggs.

The parasite load presented by infected individuals was moderate and quantified by the Kato-Katz technique only. Although the quantification of infection intensity has long been considered an important factor in the evaluation of clinical morbidity, recent studies have pointed out that the severity of the disease does not correlate only with the worm burden, as in neuroschistosomiasis and myelorradiculopathy^{18,19}. The epidemiological relevance of the infection intensity is due to the fact that it reflects the individual's potential for spreading the disease and contributing to its transmission²⁰. One of the limitations of the TF-Test® is that it is a qualitative technique; therefore, it does not allow the infection quantification. However, in some studies, quantification has been experimentally performed, as in the study by Lumina et al.²¹, in which the TF-Test® was used to diagnose intestinal parasites in sheep.

It was possible to clearly observe that the positivity rate obtained by the TF-Test® technique is directly influenced by the individual's parasite load, with rates ranging from 33.9% in those individuals with a low parasite load to 84.2% in those with a high load. This is a significant increase of 2.5 times, proving that the TF-Test® presented a lower than expected diagnostic performance, since it uses a larger amount of fecal material, which theoretically would lead to an increase in efficacy. It is important to emphasize that the TF-Test® detected 11.5% positivity in individuals who presented Kato-Katz negative results, thus demonstrating

the importance of the association of diagnostic methods for the better detection of infected individuals.

Although the TF-Test[®] has been considered poorly effective in detecting *S. mansoni* as compared to Kato-Katz, it was more sensitive to detect other intestinal parasites. This test found 46.8% of positivity for hookworm versus 22.8% with Kato-Katz; 13.8% for *Hymenolepis nana* versus 0.2% with Kato-Katz; 13.0% for *Strongyloides stercoralis*, and 28.3% for pathogenic protozoan cysts. The ability to detect helminthes larvae and protozoan cysts is a positive characteristic of TF-Test[®] in relation to Kato-Katz. The high prevalence of non-pathogenic protozoa, such as *Entamoeba coli* (74.5%), *Endolimax nana* (56.7%), and *Iodamoeba butschlii* (29.9%), indicates the precarious situation of the Maxakali people with regard to sanitary conditions, hygiene and health, since these organisms indicate fecal contamination²² and their presence is considered an indicator of the poor quality of drinking water.

The highest rates for *S. mansoni* infection were obtained in the 12-18 age group regardless of the diagnostic technique, followed by the 19-59 and 0-11 age groups, and then decreasing with age. The highest positivity rates obtained in children and young people were probably due to a higher exposure and contact with contaminated water, associated with occupational, leisure, or household activities. According to Enk et al.⁴, males in the age group between 10 and 30 years old and practicing leisure activities related to contact with unsafe water show the highest accumulative risk of infection. Our data differ from those reported by these authors, since the highest positivity rate was found in females ranging from 12-18 years old.

In general, the probable source of infection could be attributed to precarious sanitary conditions: 73.8% used water from rivers and ponds, 98.7% used untreated water, and 74.7% did not have toilets¹². Another fact would be their behavior in relation to water, as they people collectively bathe, wash clothes, and draw water from the same sources, and both men and women use a fishing basket in the water. Moreover, the semi-nomadic habits of the Maxakali people and frequent familial mobility to and from endemic regions in the Mucuri and Doce River Valleys, could also be considered as probable sources of infection¹².

Other aspects should be taken into account when applying the TF-Test[®] in epidemiological studies, such as the need to acquire kits and inputs to carry out the test, along with a centrifuge to process the samples. In spite of the Kato-Katz technique's advantages, such as cost-benefit¹⁶, simplicity, and infrastructure, it presents similar limitations of other parasitological tests, such as the need for personnel capable of microscopic reading, which is a laborious step that requires a well-trained examiner to avoid

false-positive and/or false-negative results, in addition to detecting helminthes eggs only. In contrast, the TF-Test[®] detects a broader spectrum of parasites.

It should be emphasized that determining the prevalence of schistosomiasis is directly influenced by the disease's transmission force in a given area. In areas of low endemicity²³, the number of slides and samples examined by the Kato-Katz technique needs to be increased^{4,5,10}. It was possible to detect a large number of infected individuals in this study by examining a single slide of Kato-Katz because it was carried out in an area with high endemicity.

One of the limitations of this study was the participants' low level of compliance, which can be attributed to cultural aspects inherent to this indigenous population, as well as its unfamiliarity with access to health services.

It is widely reported in the literature that the combination of diagnostic techniques or increased numbers of samples and slides made by the Kato-Katz technique increases the detection of disease from 2.5 to 4.5 times^{4,5}. In conclusion, despite the limiting factors intrinsic to each technique, the combined use of the TF-Test[®] technique with Kato-Katz resulted in an increase in the positivity rate of *S. mansoni* detection from 45.7% to 51.9% ($p < 0.05$), demonstrating the importance of the association of diagnostic methods for a better detection of infected individuals. The combination of a quantitative and a qualitative method performed with only one fecal sample collection was effective in classifying the Maxakali population as a high risk group for schistosomiasis infection. The Maxakali are in socially vulnerable conditions¹² and, as such, the results of this study are expected to act as indicators of the prevalence of schistosomiasis and assist in targeting control strategies such as basic sanitation, health education, and treatment, which need to be deployed in this area.

ACKNOWLEDGMENTS

We would like to acknowledge the indigenous leadership, the Distrito Sanitario Especial Indígena (DSEI-MG/ES), Secretaria Especial de Saúde Indígena (SESAI), to the indigenous people of the Maxakali ethnic group, to the health agents and to the technical laboratories that collaborated to carry out the diagnostic tests.
